prediction of the conversion of CO$_2$ in the falling film reactor involved complex non-linear problem of simultaneous diffusion and chemical reaction in the liquid phase. The Artificial neural network (ANN), is not fully studied and explored in the field of chemical engineering, provides an alternative method for modeling complex systems. Neural Networks are computer algorithms inspired by the way information is processed in the nervous system. An ANN is a massively parallel distributed processor that has a natural propensity for storing experimental knowledge and making it available. An important difference between neural networks and standard Information Technology (IT) solutions is their ability to learn. This learning property has yielded a new generation of algorithms that can:

- learn from the past to predict the future;
- extract rules for reasoning in complex environments;
- offer solutions when explicit algorithms and models are unavailable or too cumbersome.

Due to the complexity of falling film reactor, an alternative ANN approach was employed to model and predict the conversion of CO$_2$ in the (CO$_2$-MEA) system in falling film reactor. Artificial neural network (ANN) does not require a prior fundamental understanding of the process or phenomena being modeled, thus, eliminating the need for numerous mathematical relationships. The architecture of the network used in this research was Feed Forward Artificial Network (FFAN) and the training of the network was done using Back Propagation Neural Network (BPNN) algorithm. This research developed ANN model using adequate number of training points obtained from the experimental study.

2 - ARTIFICIAL NEURAL NETWORK (ANN)

Over the past few years, Artificial neural network (ANN) has received a great deal of attention and is now being proposed as a powerful computational tools. The structures of ANN are nervous system. The potential benefits of ANN extend beyond the high computation rates provided by massive parallelism. The application phase of ANN takes relatively little time compared to its training phase and therefore offers potentially faster solutions for problem solving. ANNs can be used to map linear as well as non-linear relations. These consist of a number of very simple and highly interconnected processors called "neurons" or processing Elements (PEs). The PEs are interconnected by connection weights. The neural net can be made to map input patterns to output patterns by adjusting or altering the connection weights. This process is called "learning" during the training phase. The ANNs program develops a model during the training, form repetitive exposures to data and readjustment of
the weights. A subgroup of PEs is called a layer in the network. The first layer is the input layer and the last layer is the output layer. The layers that are placed between the input and the output layer are called hidden layers. Each PE typically receives many signals over its incoming connections. These signals may arise from other PEs or from the external environment. A PE in a neural network receives input stimuli along its input connections and translates those stimuli into a single output response, which is then transmitted along the PEs output connections. The mathematical expression that describes the translation of the input stimulus pattern to the output response signal is called the transfer function of the PE. The network was training by Back Propagation Neural Network (BPNN) algorithm. The architecture of the BPNN is a hierarchical design consisting of fully interconnected layers of rows of processing units as shown in Fig.(1). Each unit is itself comprised of several individual PEs. This architecture does not have feedback connections, but errors are back propagated during training. In here, BPNN has forward flowing information in the prediction mode and back propagation error correction in the learning mode. Errors in the output determine measures of hidden layer output errors, which are used as a basis for adjusting the two sets of weights between the pairs of layers and recalculating the outputs is an iterative process that is carried on until the errors fall below a tolerance. The ANN program develops a model during training, from repetitive exposures to data (data could be noisy, highly nonlinear and complex) and readjustment of the weights. In BPNN, The network takes a set of inputs and produces predicted outputs, which are then compared to the actual outputs. An error signal alters the weights of all interconnections, so that subsequent predictions are closer to the actual value. Initial weights can be set randomly. Eventually, after a sufficient number of training iterations, the net learns to recognize pattern in the data or a set of weights for all interconnections. Then the trained network, with the corresponding good weights, can use the internal model to make predictions on the outputs from sets of inputs previously unknown to it. It important to note that this internal model is not based on any specification of the underlying mechanism for process, the net itself generates this model.

3- METHODOLOGY

The following steps were carried out in the development of ANN-based model used for the prediction of the CO$_2$ conversion in the falling film reactor.

3.1 – Database Generation
The network is trained by the database based on the results obtained from experimental measurements. 216 sets of data adapted to train and test the ANN model. Further quantities such as mole fraction of carbon dioxide in gaseous mixture (Y), molar concentration of the absorbent (monoethanolamine) (CMEA), volumetric flow rate of liquor MEA (QMEA) and its temperature (T) effects the conversion of CO$_2$ and they are used as input parameters to predict the conversion of CO$_2$ (the only output parameter).

3.2 – Normalizing the Raw Data Collected

Generally, majority of the effort in developing a neural network model into collecting data and preprocessing them appropriately. The standard process is to normalize the raw data. Here, the requirement is that the inputs to each input PEs should be in the between -1.0 to 1.0, inclusive and the output to each output PEs should be between 0.0 to 1.0. Normalizing the raw data avoids numerical overflows due to very or small weights. The approach adopted for normalizing the raw data is:

Normalized value of a variable = Raw value of a variable divided by the largest absolute value.

3.3 – Selection of The Number of Hidden Layer

The hidden layer abstracts the characters of the input information. Increasing the number of hidden layers, the performance of the treatment ability of a feed-forward artificial neural network will be promoted. But it may cause the complexity of training procedure, the increase of training samples and training time. Generally speaking, we should start with a system with one hidden layer and increase the number of hidden layer by requirement. For a continuous output or even a discontinuous output in some cases, a very close prediction can be obtained via a feed-forward artificial neural network with only two hidden layers. In most cases, even a feed-forward artificial neural network with one hidden layer, can reach a considerable good prediction.

3.4 - Selection of the Number of Hidden Layer Neuron

The selection of the number of the hidden layer neuron is very important and troublesome. If the number of the hidden layer neuron is fewer, the ANN cannot receive all necessary information of the modeling system and less tolerance on faults, so that it gives wrong outputs. On the contrary, the ANN may cause a phenomenon called overfitting. The overfitting is that the ANN can even recognize the noise during the training procedure. Under this circumstance, the outputs of ANN are ideal when the training samples are applied, while the outputs are not satisfied when the test samples are adopted. At the same time, ANN needs
a long time for training and running. In some cases, it may even make it hard to determine the weights. There are some theories to determine the optimum number of hidden neuron depends mostly on experience, one of them are assume that the number of hidden layer neuron should be 2N+1 to obtain reasonable output for any inputs. Here N is the number of input neuron.

3.5 – ANN Design And Training

A Feed Forward Artificial Neural Network (FFNN) trained by back propagation, is widely used based on the complexity of the problem and the size of the database, the number of hidden layer and the neurons within each hidden layer, can be varied, Fig. (1) shows a three layer ANN structure with four inputs, one hidden layer with nine neurons, and one output. The input layer that distributes the inputs to the hidden layer does not have any activation function. Mathematically the network computes; see the ANN structure shown in Fig.(1),

1. The output of the hidden layer (treating the bias as another input, but being counted as a real input of our ANN structure).
   
   \[ h_1 (j) = \text{sum} \left( w_1 (i,j) \ast U (i) , i = 1 , 5 \right) \]
   
   \[ H (j) = f (h_1 (j)) \]

2. For the output layer calculation.
   
   \[ h_2 (k) = \text{sum} \left( w_2 (j,k) \ast H(j) , j = 1 , 9 \right) \]
   
   \[ S (k) = f (h_2 (k)) \]

where, \( U(i) \) is the network input, \( S(k) \) is the network output, \( w_1(i,j) \) represents the weight connection neuron \( i \) in the input later to neuron \( j \) in the hidden layer, \( w_2(j,k) \) represents the weight connecting neuron \( j \) in the hidden layer to neuron \( k \) in the output layer, and \( f(x) \) is the neuron transfer function, for example a sigmoid \( f(x) = 1 / (1 + \exp(-x)) \), which is adapted in this research.

4 - RESULTS AND DISCUSSION

ANN of BPNN learning algorithm was used in the prediction of the conversion of \( \text{CO}_2 \) in the falling film reactor in terms of mole fraction of carbon dioxide in gaseous mixture (Y), molar concentration of the absorbent (monoethanolamine) (CMEA), volumetric flow rate of liquor MEA (QMEA) and its temperature (T). During the training process, four inputs and one output variables were used. The training data, which were concretely selected, consisted of 190 patterns as shown in Table(1). Sufficient data (26 patterns) were used as test sets as shown in Table(2) which shows that the values of \( \text{CO}_2 \) conversion predicted by ANN model...
were found to be very close to the values obtained from experimental study and the error between them were very small about 0.6%. It is essential to have enough data as training and testing sets to train and evaluated the performance of the network effectively. In the application of the backpropagation algorithm by matlab program\cite{12}, a number of different layers and processing elements were tried. It should be noted that the number of hidden layers and number of processing elements in each layer are problem dependent and are empirically selected. The time of convergence depended on the number of PEs in the hidden layer. Moreover, the addition of momentum parameter and noise factor also helped the simulation to converge. It is necessary to vary the parameters used in the neural network such as the learning rate, error tolerance, momentum parameter, and noise factor in order to get the fastest convergence. In this research, the best result was obtained using the following input parameters:

- \textbf{A} Error tolerance = 0.001
- \textbf{B} Learning parameter = 0.05
- \textbf{C} Total number of layers = 3
- \textbf{D} Total number of processing elements for every layer
  - (Input hidden output = 4 9 1)
- \textbf{E} Momentum parameter = 0.0005
- \textbf{F} Noise factor = 0.0005

\textbf{4.1- Effect of Liquid Temperature on ANN Model Behavior}

Figures (2) and (3) show the effect of liquid temperature on the conversion of carbon dioxide in monoethanolamine solution for different flow rates at constant mole fraction of CO$_2$ (Y=0.1), (Y=0.075) and constant absorbent concentration (Molarity = 3M). The temperature increase has a positive effect on CO$_2$ conversion, since increasing temperature will also increase the rate of chemical reaction and decreases the viscosity of the solution, which leads to an increase in absorption rate and consequently CO$_2$ conversion. These results are in agreement with Abid\cite{13}. Figures (4) and (5) also show the effect of liquor temperature on CO$_2$ conversion. But for different liquid concentration and at constant mole fraction of carbon dioxide (Y=0.1) and (Y=0.075) and constant liquid flow rate (Q =20 L/hr). A highest conversion is noticed at a solution of (3M) and 20 L/hr of monoethanolamine. Training data in Fig.s (2 - 5) at monoethanolamine solution flow rates (10, 15, and 20 L/hr) and monoethanolamine concentrations (1, 2, and 3 M) respectively are in solid symbols in three curves. Testing points at the intermediate conditions were on the three curves (same
curves with that of the training data). While ANN predictions at additional conditions were made at flow rates 7, 12, and 18 L/hr. It is observed that ANN testing and prediction are almost similar with that of the experimental results. It can be seen on these figures that the ANN is able to predict accurately the values of CO₂ conversion at other testing conditions (Q=7, 12, and 18 L/hr) and (CMEA=1.5 and 2.5 M).

4.2- **Effect of Mole Fraction of CO₂ in Gaseous Mixture on ANN Model Behavior**

Experimental and ANN results show a proportional relation between mole fraction of carbon dioxide in gas phase and conversion of carbon dioxide, starting from 0.05 to 0.1, this behavior is shown in Figs. (6) and (7) and are in agreement with the results of Tontiwachwuthinkul et al. [14] and Abid [13]. ANN model was able to predict the CO₂ conversion at different liquid flow rates (Q=7, 12, and 18 L/hr) which are not found in the experimental data. It is noted that ANN testing (at intermediate conditions) and prediction are almost as the same with that of experimental results.

4.3- **Effect of Absorbent Concentration on ANN Model Behavior**

Figures (8) and (9) show a comparison between the predictions obtained using the ANN model and experimental data for (CO₂ – MEA) system at different MEA solution flow rates at constant mole fraction of CO₂ (Y=0.1) and (Y=0.075) and constant liquid temperature at (T=55°C). The trend shown by the ANN model is in agreement with the recent studies which show that using of highly concentrated amine exhibit a high conversion of CO₂ but stopping at 3M which is more economic since it shows an acceptable conversion [13,15].

5 – **CONCLUSIONS**

The ANN model developed to apply on the absorption process of CO₂ gas by MEA solution in falling film reactor to predict the CO₂ conversion in a wide range of operating conditions. The values predicted by ANN model were found to be very close to the values obtained from experimental results. The average error as predicted by ANN was 0.6% which are within the acceptable level. It has demonstrated that the optimal model is a network with one hidden layer and nine neurons. Further work (experimental and CFD simulation) is required to provide a more completed database to train the network and validate its usefulness. From the results obtained the ANN models were found to give at least satisfactory, if not excellent predictions.
